

## 2-Phase, 5-Bit Adjustable, High Efficiency, Synchronous Step-Down Switching Regulator

October 1999

### FEATURES

- 2-Phase Single Output Controller
- 5-Bit VID Control Inputs  
 $V_{OUT}$ : 1.3V to 3.5V in 50mV/100mV Steps
- **Dramatically Reduces Required Input Capacitance and Power Supply Induced Noise**
- **Current Mode Control Ensures Current Sharing**
- Phase-Lockable Fixed Frequency: 150kHz to 300kHz
- **True Remote Sensing Differential Amplifier**
- OPTI-LOOP™ Compensation
- **±1% Output Voltage Accuracy**
- Wide  $V_{IN}$  Range: 4V to 36V Operation
- **High Efficiency Operation Eliminates Heat Sinks**
- Adjustable Soft-Start Current Ramping
- Internal Current Limit Foldback
- Short-Circuit Shutdown Timer with Defeat Option
- Overvoltage Soft-Latch Eliminates Nuisance Trips
- Available in 36-Lead Narrow SSOP Package

### APPLICATIONS

- Desktop Computers
- Internet/Network Servers
- Large Memory Arrays
- DC Power Distribution Systems

### DESCRIPTION

The LTC®1709 is a 5-bit VID programmable, 2-phase, single output, synchronous step-down current mode switching regulator controller that drives N-channel external power MOSFET stages in a phase-lockable fixed frequency architecture. The controller drives its two output stages 180° out of phase at frequencies up to 300kHz to minimize the RMS ripple currents in both input and output capacitors. The 2-phase technique effectively doubles the fundamental frequency, improving transient response while operating each channel at an optimum frequency for efficiency. Thermal design is also simplified.

The input and output RMS ripple current terms are significantly reduced by running the two power stages 180° out of phase. The inductors and capacitor values can also be modified to reduce size and improve transient response performance.

An internal differential amplifier provides true remote sensing of the regulated supply's positive and negative output terminals as required in high current applications.

Δ, LTC and LT are registered trademarks of Linear Technology Corporation.  
OPTI-LOOP is a trademark of Linear Technology Corporation.

### TYPICAL APPLICATION

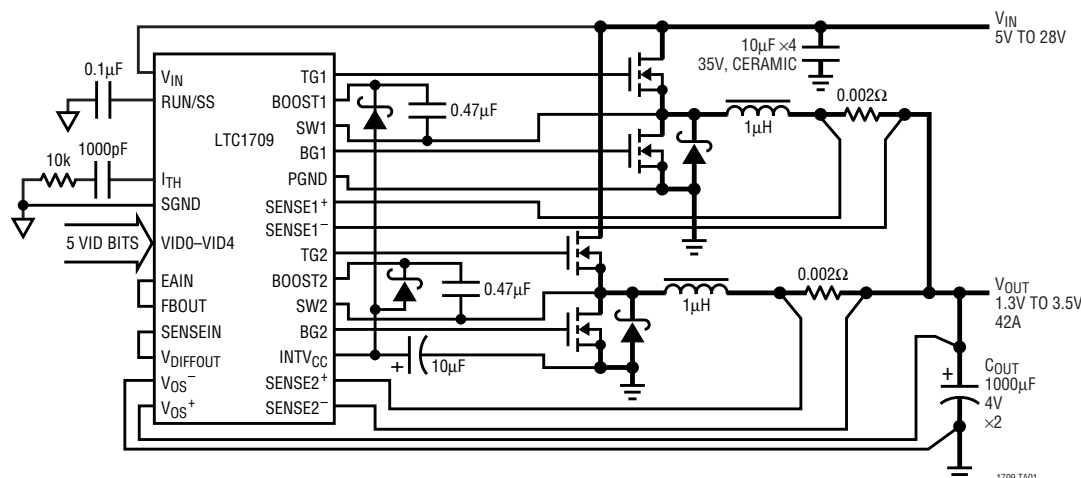

Figure 1. Surface Mount, 42A, 2-Phase Step-Down Converter

## ABSOLUTE MAXIMUM RATINGS

(Note 1)

Input Supply Voltage ( $V_{IN}$ )	36V to $-0.3V$
Topside Driver Voltages (BOOST1,2)	42V to $-0.3V$
Switch Voltage (SW1, 2)	36V to $-5V$
SENSE1 <sup>+</sup> , SENSE2 <sup>+</sup> , SENSE1 <sup>-</sup> , SENSE2 <sup>-</sup> Voltages	(1.1)INTV <sub>CC</sub> to $-0.3V$
EAIN, $V_{OS}^+$ , $V_{OS}^-$ , EXT <sub>CC</sub> , INT <sub>CC</sub> , RUN/SS, AMPMD, $V_{BIAS}$ , ATTENIN, ATTENOUT, VID0–VID4, Voltages	7V to $-0.3V$
Boosted Driver Voltage (BOOST-SW)	7V to $-0.3V$
PLLFLTR, PLLIN, $V_{DIFFOUT}$ Voltages	INTV <sub>CC</sub> to $-0.3V$
$I_{TH}$ Voltage	2.7V to $-0.3V$
Peak Output Current <1 $\mu$ s(TGL1,2, BG1,2)	3A
INTV <sub>CC</sub> RMS Output Current	50mA
Operating Ambient Temperature Range (Note 2)	$-40^{\circ}C$ to $85^{\circ}C$
Junction Temperature (Note 3)	$125^{\circ}C$
Storage Temperature Range	$-65^{\circ}C$ to $150^{\circ}C$
Lead Temperature (Soldering, 10 sec)	$300^{\circ}C$

**Note 1:** Absolute Maximum Ratings are those values beyond which the life of a device may be impaired.

**Note 2:** The LTC1709EG is guaranteed to meet performance specifications from  $0^\circ\text{C}$  to  $70^\circ\text{C}$ . Specifications over the  $-40^\circ\text{C}$  to  $85^\circ\text{C}$  operating temperature range are assured by design, characterization and correlation with statistical process controls.

**Note 3:**  $T_J$  is calculated from the ambient temperature  $T_A$  and power dissipation  $P_D$  according to the following formulas:

$$\text{LTC1709EG: } T_J = T_A + (P_D \cdot 85^\circ\text{C/W})$$

**Note 4:** The LTC1709 is tested in a feedback loop that serves  $V_{ITH}$  to a specified voltage and measures the resultant  $V_{EAIN}$ .

**Note 5:** Dynamic supply current is higher due to the gate charge being delivered at the switching frequency. See Applications Information.

**Note 6:** Rise and fall times are measured using 10% and 90% levels. Delay times are measured using 50% levels.

**Note 7:** The minimum on-time condition corresponds to the on inductor peak-to-peak ripple current  $\geq 40\%$   $I_{MAX}$  (see Minimum On-Time Considerations in the Applications Information section).

**Note 8:** Each built-in pull-up resistor attached to the VID inputs also has a series diode to allow input voltages higher than the  $VIDV_{CC}$  supply without damage or clamping (see the Applications Information section).

**Note 9:** When the AMPMD pin is high, the IC pins are connected directly to the internal op amp inputs. When the AMPMD pin is low, internal MOSFET switches connect four  $40k$  resistors around the op amp to create a standard unity-gain differential amp.

## PIN FUNCTIONS

**RUN/SS (Pin 1):** Combination of Soft-Start, Run Control Input and Short-Circuit Detection Timer. A capacitor to ground at this pin sets the ramp time to full current output. Forcing this pin below  $0.8\text{V}$  causes the IC to shut down all internal circuitry. All functions are disabled in shutdown.

**SENSE1<sup>+</sup>, SENSE2<sup>+</sup> (Pins 2,14):** The (+) Input to Each Differential Current Comparator. The  $I_{TH}$  pin voltage and built-in offsets between SENSE<sup>-</sup> and SENSE<sup>+</sup> pins in conjunction with  $R_{SENSE}$  set the current trip threshold.

**SENSE1<sup>-</sup>, SENSE2<sup>-</sup> (Pins 3, 13):** The (–) Input to the Differential Current Comparators.

**EAIN (Pin 4):** Input to the Error Amplifier that compares the feedback voltage to the internal  $0.8\text{V}$  reference voltage. This pin is normally connected to a resistive divider from the output of the differential amplifier (DIFFOUT).

**PLLFLTR (Pin 5):** The Phase-Locked Loop's Low Pass Filter is tied to this pin. Alternatively, this pin can be driven with an AC or DC voltage source to vary the frequency of the internal oscillator.

## PIN FUNCTIONS

**PLLIN (Pin 6):** External Synchronization Input to Phase Detector. This pin is internally terminated to SGND with 50k $\Omega$ . The phase-locked loop will force the rising top gate signal of controller 1 to be synchronized with the rising edge of the PLLIN signal.

**NC (Pins 7, 36):** Do not connect.

**I<sub>TH</sub> (Pin 8):** Error Amplifier Output and Switching Regulator Compensation Point. Both current comparator's thresholds increase with this control voltage. The normal voltage range of this pin is from 0V to 2.4V

**SGND (Pin 9):** Signal Ground, common to both controllers. Route separately to the PGND pin.

**V<sub>DIFFOUT</sub> (Pin 10):** Output of a Differential Amplifier that provides true remote output voltage sensing. This pin normally drives an external resistive divider that sets the output voltage.

**V<sub>OS</sub><sup>-</sup>, V<sub>OS</sub><sup>+</sup> (Pins 11, 12):** Inputs to an Operational Amplifier. Internal precision resistors capable of being electronically switched in or out can configure it as a differential amplifier or an uncommitted Op Amp.

**ATTENOUT (Pin 15):** Voltage Feedback Signal Resistively Divided According to the VID Programming Code.

**ATTENIN (Pin 16):** The Input to the VID Controlled Resistive Divider.

**VID0–VID4 (Pins 17, 18, 19, 20, 21):** VID Control Logic Input Pins.

**V<sub>BIAS</sub> (Pin 22):** Supply Pin for the VID Control Circuit.

**AMPMD (Pin 23):** This Logic Input pin controls the connections of internal precision resistors that configure the operational amplifier as a unity-gain differential amplifier.

**TG2, TG1 (Pins 24, 35):** High Current Gate Drives for Top N-Channel MOSFETS. These are the outputs of floating drivers with a voltage swing equal to INTV<sub>CC</sub> superimposed on the switch node voltage SW.

**SW2, SW1 (Pins 25, 34):** Switch Node Connections to Inductors. Voltage swing at these pins is from a Schottky diode (external) voltage drop below ground to V<sub>IN</sub>.

**BOOST2, BOOST1 (Pins 26, 33):** Bootstrapped Supplies to the Topside Floating Drivers. External capacitors are connected between the boost and switch pins, and Schottky diodes are connected between the boost and INTV<sub>CC</sub> pins.

**BG2, BG1 (Pins 27, 31):** High Current Gate Drives for Bottom N-Channel MOSFETS. Voltage swing at these pins is from ground to INTV<sub>CC</sub>.

**PGND (Pin 28):** Driver Power Ground, connects to sources of bottom N-channel MOSFETS and the (–) terminals of C<sub>IN</sub>.

**INTV<sub>CC</sub> (Pin 29):** Output of the Internal 5V Linear Low Dropout Regulator and the EXTV<sub>CC</sub> Switch. The driver and control circuits are powered from this voltage source. Decouple to power ground with a 1 $\mu$ F ceramic capacitor placed directly adjacent to the IC and minimum of 4.7 $\mu$ F additional tantalum or other low ESR capacitor.

**EXTV<sub>CC</sub> (Pin 30):** External Power Input to an Internal Switch. This switch closes and supplies INTV<sub>CC</sub>, bypassing the internal low dropout regulator whenever EXTV<sub>CC</sub> is higher than 4.7V. See EXTV<sub>CC</sub> Connection in the Applications Information section. Do not exceed 7V on this pin and ensure V<sub>EXTVCC</sub>  $\leq$  V<sub>INTVCC</sub>.

**V<sub>IN</sub> (Pin 32):** Main Supply Pin. Should be closely decoupled to the IC's signal ground pin.

## OPERATION (Refer to Functional Diagram)

### Main Control Loop

The LTC1709 uses a constant frequency, current mode step-down architecture with inherent current sharing. During normal operation, the top MOSFET is turned on each cycle when the oscillator sets the RS latch, and turned off when the main current comparator, I1, resets the RS latch. The peak inductor current at which I1 resets the RS latch is controlled by the voltage on the  $I_{TH}$  pin, which is the output of the error amplifier EA. The differential amplifier, A1, produces a signal equal to the differential voltage sensed across the output capacitor but re-references it to the internal signal ground (SGND) reference. The EAIN pin receives a portion of this voltage feedback signal at the DIFFOUT as determined by VID logic input pins (VID0 to VID4) and is compared to the internal reference voltage by the EA. When the load current increases, it causes a slight decrease in the EAIN pin voltage relative to the 0.8V reference, which in turn causes the  $I_{TH}$  voltage to increase until the average inductor current matches the new load current. After the top MOSFET has turned off, the bottom MOSFET is turned on for the rest of the period.

The top MOSFET drivers are biased from floating bootstrap capacitor  $C_B$ , which normally is recharged during each off cycle through an external Schottky diode. When  $V_{IN}$  decreases to a voltage close to  $V_{OUT}$ , however, the loop may enter dropout and attempt to turn on the top MOSFET continuously. A dropout detector detects this condition and forces the top MOSFET to turn off for about 400ns every 10th cycle to recharge the bootstrap capacitor,  $C_B$ .

The main control loop is shut down by pulling Pin 1 (RUN/SS) low. Releasing RUN/SS allows an internal 1.2 $\mu$ A current source to charge soft-start capacitor  $C_{SS}$ . When  $C_{SS}$  reaches 1.5V, the main control loop is enabled with the  $I_{TH}$  voltage clamped at approximately 30% of its maximum value. As  $C_{SS}$  continues to charge,  $I_{TH}$  is gradually released allowing normal operation to resume. When the RUN/SS pin is low, all LTC1709 functions are shut down. If  $V_{OUT}$  has not reached 70% of its nominal value when  $C_{SS}$  has charged to 4.1V, an overcurrent latching can be invoked as described in the Applications Information section.

### Low Current Operation

The LTC1709 operates in a continuous, PWM control mode. The resulting operation at low output currents optimizes transient response at the expense of substantial negative inductor current during the latter part of the period. The level of ripple current is determined by the inductor value, input voltage, output voltage, and frequency of operation.

### Frequency Synchronization

The phase-locked loop allows the internal oscillator to be synchronized to an external source via the PLLIN pin. The output of the phase detector at the PLLFLTR pin is also the DC frequency control input of the oscillator that operates over a 140kHz to 310kHz range corresponding to a DC voltage input from 0V to 2.4V. When locked, the PLL aligns the turn on of the top MOSFET to the rising edge of the synchronizing signal. When PLLIN is left open, the PLLFLTR pin goes low, forcing the oscillator to minimum frequency.

Input capacitance ESR requirements and efficiency losses are substantially reduced because the peak current drawn from the input capacitor is effectively divided by two and power loss is proportional to the RMS current squared. A two stage, single output voltage implementation can reduce input path power loss by 75% and radically reduce the required RMS current rating of the input capacitor(s).

### INTV<sub>CC</sub>/EXTV<sub>CC</sub> Power

Power for the top and bottom MOSFET drivers and most of the IC circuitry is derived from INTV<sub>CC</sub>. When the EXTV<sub>CC</sub> pin is left open, an internal 5V low dropout regulator supplies INTV<sub>CC</sub> power. If the EXTV<sub>CC</sub> pin is taken above 4.7V, the 5V regulator is turned off and an internal switch is turned on connecting EXTV<sub>CC</sub> to INTV<sub>CC</sub>. This allows the INTV<sub>CC</sub> power to be derived from a high efficiency external source such as the output of the regulator itself or a secondary winding, as described in the Applications Information section. An external Schottky diode can be used to minimize the voltage drop from EXTV<sub>CC</sub> to INTV<sub>CC</sub> in applications requiring greater than the specified INTV<sub>CC</sub> current. Voltages up to 7V can be applied to EXTV<sub>CC</sub> for additional gate drive capability.

## OPERATION (Refer to Functional Diagram)

### Differential Amplifier

This amplifier provides true differential output voltage sensing. Sensing both  $V_{OUT}^+$  and  $V_{OUT}^-$  benefits regulation in high current applications and/or applications having electrical interconnection losses. The AMPMD pin allows selection of internal, precision feedback resistors for high common mode rejection differencing applications, or direct access to the actual amplifier inputs without these internal feedback resistors for other applications. The AMPMD pin is grounded to connect the internal precision resistors in a unity-gain differencing application, or tied to the INTV<sub>CC</sub> pin to bypass the internal resistors and make the amplifier inputs directly available. The amplifier is a unity-gain stable, 2MHz gain-bandwidth, >120dB open-loop gain design. The amplifier has an output slew rate of 5V/μs and is capable of driving capacitive loads with an output RMS current typically up to 35mA. The amplifier is not capable of sinking current and therefore must be resistively loaded to do so.

### Short-Circuit Detection

The RUN/SS capacitor is used initially to limit the inrush current from the input power source. Once the controllers have been given time, as determined by the capacitor on the RUN/SS pin, to charge up the output capacitors and provide full-load current, the RUN/SS capacitor is then used as a short-circuit timeout circuit. If the output voltage falls to less than 70% of its nominal output voltage the RUN/SS capacitor begins discharging assuming that the output is in a severe overcurrent and/or short-circuit condition. If the condition lasts for a long enough period as determined by the size of the RUN/SS capacitor, the controller will be shut down until the RUN/SS pin voltage is recycled. This built-in latchoff can be overridden by providing a current >5μA at a compliance of 5V to the RUN/SS pin. This current shortens the soft-start period but also prevents net discharge of the RUN/SS capacitor during a severe overcurrent and/or short-circuit condition. Foldback current limiting is activated when the output voltage falls below 70% of its nominal level whether or not the short-circuit latchoff circuit is enabled.

## APPLICATIONS INFORMATION

The basic LTC1709 application circuit is shown in Figure 1 on the first page. External component selection begins with the selection of the inductor(s) based on ripple current requirements and continues with the R<sub>SENSE1, 2</sub> resistor selection using the calculated peak inductor current and/or maximum current limit. Next, the power MOSFETs and D1 and D2 are selected. The operating frequency and the inductor are chosen based mainly on the amount of ripple current. Finally, C<sub>IN</sub> is selected for its ability to handle the input ripple current (that PolyPhase™ operation minimizes) and C<sub>OUT</sub> is chosen with low enough ESR to meet the output ripple voltage and load step specifications (also minimized with PolyPhase). Current mode architecture provides inherent current sharing between output stages. The circuit shown in Figure 1 can be configured for operation up to an input voltage of 28V (limited by the external MOSFETs).

### R<sub>SENSE</sub> Selection For Output Current

R<sub>SENSE1, 2</sub> are chosen based on the required output

current. The LTC1709 current comparator has a maximum threshold of 75mV/R<sub>SENSE</sub> and an input common mode range of SGND to 1.1( INTV<sub>CC</sub>). The current comparator threshold sets the peak inductor current, yielding a maximum average output current I<sub>MAX</sub> equal to the peak value less half the peak-to-peak ripple current, ΔI<sub>L</sub>.

Allowing a margin for variations in the LTC1709 and external component values yields:

$$R_{SENSE} = 2(50\text{mV}/I_{MAX})$$

### Operating Frequency

The LTC1709 uses a constant frequency, phase-lockable architecture with the frequency determined by an internal capacitor. This capacitor is charged by a fixed current plus an additional current which is proportional to the voltage applied to the PLLFLTR pin. Refer to Phase-Locked Loop and Frequency Synchronization in the Applications Information section for additional information.

PolyPhase is a registered trademark of Linear Technology Corporation.

## APPLICATIONS INFORMATION

A graph for the voltage applied to the PLLFLTR pin vs frequency is given in Figure 2. As the operating frequency is increased the gate charge losses will be higher, reducing efficiency (see Efficiency Considerations). The maximum switching frequency is approximately 310kHz.

Figure 2. Operating Frequency vs  $V_{PLLFLTR}$

### Inductor Value Calculation and Output Ripple Current

The operating frequency and inductor selection are inter-related in that higher operating frequencies allow the use of smaller inductor and capacitor values. So why would anyone ever choose to operate at lower frequencies with larger components? The answer is efficiency. A higher frequency generally results in lower efficiency because MOSFET gate charge and transition losses increase directly with frequency. In addition to this basic tradeoff, the effect of inductor value on ripple current and low current operation must also be considered. The PolyPhase approach reduces both input and output ripple currents while optimizing individual output stages to run at a lower fundamental frequency, enhancing efficiency.

The inductor value has a direct effect on ripple current. The inductor ripple current  $\Delta I_L$  per individual section,  $N$ , decreases with higher inductance or frequency and increases with higher  $V_{IN}$  or  $V_{OUT}$ :

$$\Delta I_L = \frac{V_{OUT}}{fL} \left( 1 - \frac{V_{OUT}}{V_{IN}} \right)$$

where  $f$  is the individual output stage operating frequency.

In a 2-phase converter, the net ripple current seen by the output capacitor is much smaller than the individual inductor ripple currents due to ripple cancellation. The details on how to calculate the net output ripple current can be found in Application Note 77.

Figure 3 shows the net ripple current seen by the output capacitors for the 1- and 2- phase configurations. The output ripple current is plotted for a fixed output voltage as the duty factor is varied between 10% and 90% on the x-axis. The output ripple current is normalized against the inductor ripple current at zero duty factor. The graph can be used in place of tedious calculations, simplifying the design process.

Accepting larger values of  $\Delta I_L$  allows the use of low inductances, but can result in higher output voltage ripple. A reasonable starting point for setting ripple current is  $\Delta I_L = 0.4(I_{OUT})/2$ , where  $I_{OUT}$  is the total load current. Remember, the maximum  $\Delta I_L$  occurs at the maximum input voltage. The individual inductor ripple currents are determined by the inductor, input and output voltages.

Figure 3. Normalized Output Ripple Current vs Duty Factor  
 $[I_{RMS} \approx 0.3 (\Delta I_{O(P-P)})]$

### Inductor Core Selection

Once the value for  $L1$  and  $L2$  is known, the type of inductor must be selected. High efficiency converters generally cannot afford the core loss found in low cost powdered iron cores, forcing the use of more expensive ferrite, molypermalloy, or Kool M $\mu$ ® cores. Actual core loss is independent of core size for a fixed inductor value, but it

Kool M $\mu$  is a registered trademark of Magnetics, Inc.

## APPLICATIONS INFORMATION

is very dependent on inductance selected. As inductance increases, core losses go down. Unfortunately, increased inductance requires more turns of wire and therefore copper losses will increase.

Ferrite designs have very low core loss and are preferred at high switching frequencies, so design goals can concentrate on copper loss and preventing saturation. Ferrite core material saturates “hard,” which means that inductance collapses abruptly when the peak design current is exceeded. This results in an abrupt increase in inductor ripple current and consequent output voltage ripple. *Do not allow the core to saturate!*

Molypermalloy (from Magnetics, Inc.) is a very good, low loss core material for toroids, but it is more expensive than ferrite. A reasonable compromise from the same manufacturer is Kool M $\mu$ . Toroids are very space efficient, especially when you can use several layers of wire. Because they lack a bobbin, mounting is more difficult. However, designs for surface mount are available which do not increase the height significantly.

### Power MOSFET, D1 and D2 Selection

Two external power MOSFETs must be selected for each controller with the LTC1709: One N-channel MOSFET for the top (main) switch, and one N-channel MOSFET for the bottom (synchronous) switch.

The peak-to-peak drive levels are set by the INTV<sub>CC</sub> voltage. This voltage is typically 5V during start-up (see EXT<sub>V</sub><sub>CC</sub> Pin Connection). Consequently, logic-level threshold MOSFETs must be used in most applications. The only exception is if low input voltage is expected ( $V_{IN} < 5V$ ); then, sublogic-level threshold MOSFETs ( $V_{GS(TH)} < 1V$ ) should be used. Pay close attention to the BV<sub>DSS</sub> specification for the MOSFETs as well; most of the logic-level MOSFETs are limited to 30V or less.

Selection criteria for the power MOSFETs include the “ON” resistance  $R_{DS(ON)}$ , reverse transfer capacitance  $C_{RSS}$ , input voltage, and maximum output current. When the LTC1709 is operating in continuous mode the duty factors for the top and bottom MOSFETs of each output stage are given by:

$$\text{Main Switch Duty Cycle} = \frac{V_{OUT}}{V_{IN}}$$

$$\text{Synchronous Switch Duty Cycle} = \left( \frac{V_{IN} - V_{OUT}}{V_{IN}} \right)$$

The MOSFET power dissipations at maximum output current are given by:

$$P_{MAIN} = \frac{V_{OUT}}{V_{IN}} \left( \frac{I_{MAX}}{2} \right)^2 (1 + \delta) R_{DS(ON)} + k(V_{IN})^2 \left( \frac{I_{MAX}}{2} \right) (C_{RSS})(f)$$

$$P_{SYNC} = \frac{V_{IN} - V_{OUT}}{V_{IN}} \left( \frac{I_{MAX}}{2} \right)^2 (1 + \delta) R_{DS(ON)}$$

where  $\delta$  is the temperature dependency of  $R_{DS(ON)}$  and  $k$  is a constant inversely related to the gate drive current.

Both MOSFETs have  $I^2R$  losses but the topside N-channel equation includes an additional term for transition losses, which peak at the highest input voltage. For  $V_{IN} < 20V$  the high current efficiency generally improves with larger MOSFETs, while for  $V_{IN} > 20V$  the transition losses rapidly increase to the point that the use of a higher  $R_{DS(ON)}$  device with lower  $C_{RSS}$  actually provides higher efficiency. The synchronous MOSFET losses are greatest at high input voltage when the top switch duty factor is low or during a short-circuit when the synchronous switch is on close to 100% of the period.

The term  $(1 + \delta)$  is generally given for a MOSFET in the form of a normalized  $R_{DS(ON)}$  vs. Temperature curve, but  $\delta = 0.005/^{\circ}C$  can be used as an approximation for low voltage MOSFETs.  $C_{RSS}$  is usually specified in the MOSFET characteristics. The constant  $k = 1.7$  can be used to estimate the contributions of the two terms in the main switch dissipation equation.

The Schottky diodes, D1 and D2 shown in Figure 1 conduct during the dead-time between the conduction of the two large power MOSFETs. This helps prevent the body diode

## APPLICATIONS INFORMATION

of the bottom MOSFET from turning on, storing charge during the dead-time, and requiring a reverse recovery period which would reduce efficiency. A 1A to 3A Schottky (depending on output current) diode is generally a good compromise for both regions of operation due to the relatively small average current. Larger diodes result in additional transition losses due to their larger junction capacitance.

### C<sub>IN</sub> and C<sub>OUT</sub> Selection

In continuous mode, the source current of each top N-channel MOSFET is a square wave of duty cycle  $V_{OUT}/V_{IN}$ . A low ESR input capacitor sized for the maximum RMS current must be used. The details of a closed form equation can be found in Application Note 77. Figure 4 shows the input capacitor ripple current for a 2-phase configuration with the output voltage fixed and input voltage varied. The input ripple current is normalized against the DC output current. The graph can be used in place of tedious calculations. The minimum input ripple current can be achieved when the input voltage is twice the output voltage

In the graph of Figure 4, the 2-phase local maximum input RMS capacitor currents are reached when:

$$\frac{V_{OUT}}{V_{IN}} = \frac{2k-1}{4}$$

where  $k = 1, 2$ .

Figure 4. Normalized RMS Input Ripple Current vs Duty Factor for 1 and 2 Output Stages

These worst-case conditions are commonly used for design because even significant deviations do not offer much relief. Note that capacitor manufacturer's ripple current ratings are often based on only 2000 hours of life. This makes it advisable to further derate the capacitor, or to choose a capacitor rated at a higher temperature than required. Several capacitors may also be paralleled to meet size or height requirements in the design. Always consult the capacitor manufacturer if there is any question.

It is important to note that the efficiency loss is proportional to the input RMS current *squared* and therefore a 2-phase implementation results in 75% less power loss when compared to a single phase design. Battery/input protection fuse resistance (if used), PC board trace and connector resistance losses are also reduced by the reduction of the input ripple current in a 2-phase system. The required amount of input capacitance is further reduced by the factor, 2, due to the effective increase in the frequency of the current pulses.

The selection of C<sub>OUT</sub> is driven by the required effective series resistance (ESR). Typically once the ESR requirement has been met, the RMS current rating generally far exceeds the I<sub>RIPPLE(P-P)</sub> requirements. The steady state output ripple ( $\Delta V_{OUT}$ ) is determined by:

$$\Delta V_{OUT} \approx \Delta I_{RIPPLE} \left( ESR + \frac{1}{16fC_{OUT}} \right)$$

Where  $f$  = operating frequency of each stage, C<sub>OUT</sub> = output capacitance and  $\Delta I_{RIPPLE}$  = combined inductor ripple currents.

The output ripple varies with input voltage since  $\Delta I_L$  is a function of input voltage. The output ripple will be less than 50mV at max  $V_{IN}$  with  $\Delta I_L = 0.4I_{OUT(MAX)}/2$  assuming:

$$C_{OUT} \text{ required ESR} < 4(R_{SENSE}) \text{ and}$$

$$C_{OUT} > 1/(16f)(R_{SENSE})$$

The emergence of very low ESR capacitors in small, surface mount packages makes very physically small implementations possible. The ability to externally compensate the switching regulator loop using the I<sub>TH</sub> pin (OPTI-LOOP compensation) allows a much wider selection of

## APPLICATIONS INFORMATION

output capacitor types. OPTI-LOOP compensation effectively removes constraints on output capacitor ESR. The impedance characteristics of each capacitor type are significantly different than an ideal capacitor and therefore require accurate modeling or bench evaluation during design.

Manufacturers such as Nichicon, United Chemicon and Sanyo should be considered for high performance through-hole capacitors. The OS-CON semiconductor dielectric capacitor available from Sanyo and the Panasonic SP surface mount types have the lowest (ESR)(size) product of any aluminum electrolytic at a somewhat higher price. An additional ceramic capacitor in parallel with OS-CON type capacitors is recommended to reduce the inductance effects.

In surface mount applications, multiple capacitors may have to be paralleled to meet the ESR or RMS current handling requirements of the application. Aluminum electrolytic and dry tantalum capacitors are both available in surface mount configurations. New special polymer surface mount capacitors offer very low ESR also but have much lower capacitive density per unit volume. In the case of tantalum, it is critical that the capacitors are surge tested for use in switching power supplies. Several excellent choices are the AVX TPS, AVX TPSV or the KEMET T510 series of surface mount tantalums, available in case heights ranging from 2mm to 4mm. Other capacitor types include Sanyo OS-CON, Nichicon PL series and Sprague 595D series. Consult the manufacturer for other specific recommendations. A combination of capacitors will often result in maximizing performance and minimizing overall cost and size.

### INTV<sub>CC</sub> Regulator

An internal P-channel low dropout regulator produces 5V at the INTV<sub>CC</sub> pin from the V<sub>IN</sub> supply pin. The INTV<sub>CC</sub> regulator powers the drivers and internal circuitry of the LTC1709. The INTV<sub>CC</sub> pin regulator can supply up to 50mA peak and must be bypassed to power ground with a minimum of 4.7μF tantalum or electrolytic capacitor. An additional 1μF ceramic capacitor placed very close to the IC is recommended due to the extremely high instantaneous currents required by the MOSFET gate drivers.

High input voltage applications in which large MOSFETs are being driven at high frequencies may cause the maximum junction temperature rating for the LTC1709 to be exceeded. The supply current is dominated by the gate charge supply current, in addition to the current drawn from the differential amplifier output. The gate charge is dependent on operating frequency as discussed in the Efficiency Considerations section. The supply current can either be supplied by the internal 5V regulator or via the EXTV<sub>CC</sub> pin. When the voltage applied to the EXTV<sub>CC</sub> pin is less than 4.7V, all of the INTV<sub>CC</sub> load current is supplied by the internal 5V linear regulator. Power dissipation for the IC is higher in this case by (I<sub>IN</sub>)(V<sub>IN</sub> – INTV<sub>CC</sub>) and efficiency is lowered. The junction temperature can be estimated by using the equations given in Note 1 of the Electrical Characteristics. For example, the LTC1709 V<sub>IN</sub> current is limited to less than 24mA from a 24V supply:

$$T_J = 70^{\circ}\text{C} + (24\text{mA})(24\text{V})(85^{\circ}\text{C/W}) = 119^{\circ}\text{C}$$

Use of the EXTV<sub>CC</sub> pin reduces the junction temperature to:

$$T_J = 70^{\circ}\text{C} + (24\text{mA})(5\text{V})(85^{\circ}\text{C/W}) = 80.2^{\circ}\text{C}$$

The input supply current should be measured while the controller is operating in continuous mode at maximum V<sub>IN</sub> and the power dissipation calculated in order to prevent the maximum junction temperature from being exceeded.

### EXTV<sub>CC</sub> Connection

The LTC1709 contains an internal P-channel MOSFET switch connected between the EXTV<sub>CC</sub> and INTV<sub>CC</sub> pins. When the voltage applied to EXTV<sub>CC</sub> rises above 4.7V, the internal regulator is turned off and an internal switch closes, connecting the EXTV<sub>CC</sub> pin to the INTV<sub>CC</sub> pin thereby supplying internal power to the IC. The switch remains closed as long as the voltage applied to EXTV<sub>CC</sub> remains above 4.5V. This allows the MOSFET driver and control power to be derived from the output during normal operation (4.7V < V<sub>EXTVCC</sub> < 7V) and from the internal regulator when the output is out of regulation (start-up, short-circuit). Do not apply greater than 7V to the EXTV<sub>CC</sub> pin and ensure that EXTV<sub>CC</sub> < V<sub>IN</sub> + 0.3V when using the application circuits shown. If an external voltage source is

## APPLICATIONS INFORMATION

amplifier corrects for DC drops in both the power and ground paths. The differential amplifier output signal is divided down and compared with the internal precision 0.8V voltage reference by the error amplifier.

The differential amplifier can be used in either of two configurations according to the voltage applied to the AMPMD pin. The first configuration with the connections illustrated in the Functional Diagram, utilizes a set of internal, precision resistors to enable precision instrumentation-type measurement of the output voltage. This configuration is activated when the AMPMD pin is tied to ground. When the AMPMD pin is tied to  $INTV_{CC}$ , the resistors are disconnected and the amplifier inputs are made directly available. It can be used for general uses if the amplifier is not required for true remote sensing. The amplifier has a 0V to 3V common mode input range limitation due to the internal switching of its inputs. The output uses an NPN emitter follower without any internal pull-down current. A DC resistive load to ground is required in order to sink current. The output will swing from 0V to 10V ( $V_{IN} \geq 11V$ ).

### Output Voltage Programming

The output voltage is digitally set to levels between 1.3V and 3.5V using the voltage identification (VID) logic inputs VID0 to VID4. The internal 5-bit DAC configured as a precision resistive voltage divider sets the output voltage in 100mV or 50mV increments according to Table 1.

The VID codes are engineered to be compatible with Intel Pentium® II and Pentium III processor specifications for output voltages from 1.3V to 3.5V.

The LSB (VID0) represents 50mV or 100mV increments depending on the MSB. The MSB is VID4.

Between the ATTENOUT pin and ground is a variable resistor, R1, whose value is controlled by the five VID input pins (VID0 to VID4). Another resistor, R2, between the ATTENIN and the ATTENOUT pins completes the resistive divider. The output voltage is thus set by the ratio of  $(R1 + R2)$  to R1.

**Table 1. VID Output Voltage Programming**

VID4	VID3	VID2	VID1	VID0	V <sub>OUT</sub> (V)
1	0	0	0	0	3.50V
1	0	0	0	1	3.40V

0	1	1	1	1	1.30V

\* Represents codes without a defined output voltage as specified in Intel specifications. The LTC1709 interprets these codes as a valid input and produces an output voltage as follows: (11111) = 2V

Each VID digital input is pulled up by a 40k resistor in series with a diode from  $V_{BIAS}$ . Therefore, it must be grounded to get a digital low input, and can be either

## APPLICATIONS INFORMATION

floated or connected to  $V_{BIAS}$  to get a digital high input. The series diode is used to prevent the digital inputs from being damaged or clamped if they are driven higher than  $V_{BIAS}$ . The digital inputs accept CMOS voltage levels.

$V_{BIAS}$  is the supply voltage for the VID section. It is normally connected to  $INTV_{CC}$  but can be driven from other sources. If it is driven from another source, that source MUST be in the range of 2.7V to 5.5V and MUST be alive prior to enabling the LTC1709.

### Soft-Start/Run Function

The RUN/SS pin provides three functions: 1) Run/Shutdown, 2) soft-start and 3) a defeatable short-circuit latching timer. Soft-start reduces the input power sources' surge currents by gradually increasing the controller's current limit  $I_{TH(MAX)}$ . The latching timer prevents very short, extreme load transients from tripping the overcurrent latch. A small pull-up current ( $>5\mu A$ ) supplied to the RUN/SS pin will prevent the overcurrent latch from operating. The following explanation describes how the functions operate.

An internal  $1.2\mu A$  current source charges up the soft-start capacitor,  $C_{SS}$ . When the voltage on RUN/SS reaches 1.5V, the controller is permitted to start operating. As the voltage on RUN/SS increases from 1.5V to 3.0V, the internal current limit is increased from  $25mV/R_{SENSE}$  to  $75mV/R_{SENSE}$ . The output current limit ramps up slowly, taking an additional  $1.4s/\mu F$  to reach full current. The output current thus ramps up slowly, reducing the starting surge current required from the input power supply. If RUN/SS has been pulled all the way to ground there is a delay before starting of approximately:

$$t_{DELAY} = \frac{1.3V}{1.2\mu A} C_{SS} = (1.1s / \mu F) C_{SS}$$

The time for the output current to ramp up is then:

$$t_{RAMP} = \frac{3V - 1.3V}{1.2\mu A} C_{SS} = (1.4s / \mu F) C_{SS}$$

By pulling both RUN/SS controller pins below 0.8V the LTC1709 is put into low current shutdown ( $I_Q < 40\mu A$ ). The RUN/SS pins can be driven directly from logic as shown in

Figure 6. Diode D1 in Figure 6 reduces the start delay but allows  $C_{SS}$  to ramp up slowly providing the soft-start function. The RUN/SS pin has an internal 6V zener clamp (see Functional Diagram).

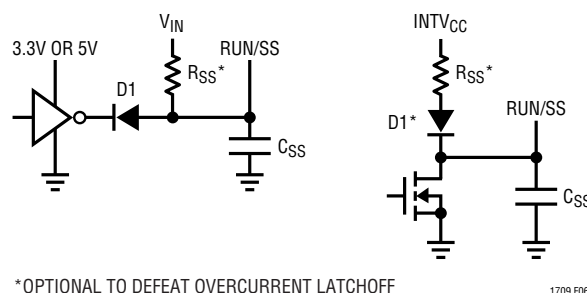

Figure 6. RUN/SS Pin Interfacing

### Fault Conditions: Overcurrent Latching

The RUN/SS pin also provides the ability to latch off the controllers when an overcurrent condition is detected. The RUN/SS capacitor is used initially to limit the inrush current of both controllers. After the controllers have been started and been given adequate time to charge up the output capacitor and provide full load current, the RUN/SS capacitor is used for a short-circuit timer. If the output voltage falls to less than 70% of its nominal value, after  $C_{SS}$  reaches 4.1V, the RUN/SS capacitor begins discharging on the assumption that the output is in a severe overcurrent condition. If the condition lasts for a long enough period as determined by the size of the RUN/SS capacitor, the controller will be shut down until the RUN/SS pin voltage is recycled. If the overload occurs during start-up, the time can be approximated by:

$$T_{LO1} \approx (C_{SS} \cdot 0.6V) / (1.2\mu A) = 5 \cdot 10^5 (C_{SS})$$

If the overload occurs after start-up the voltage on the RUN/SS capacitor will continue charging and will provide additional time before latching off:

$$T_{LO2} \approx (C_{SS} \cdot 3V) / (1.2\mu A) = 2.5 \cdot 10^6 (C_{SS})$$

This built-in overcurrent latching can be overridden by providing a pull-up resistor,  $R_{SS}$ , to the RUN/SS pin as shown in Figure 6. This resistance shortens the soft-start period and prevents the discharge of the RUN/SS capacitor during a severe overcurrent and/or short-circuit condition. When deriving the  $5\mu A$  current from  $V_{IN}$  as in the figure, current latching is always defeated. The diode

## APPLICATIONS INFORMATION

connecting of this pull-up resistor to  $INTV_{CC}$ , as in Figure 6, eliminates any extra supply current during shut-down while eliminating the  $INTV_{CC}$  loading from preventing the controller from starting up.

Why should you defeat current latchoff? During the prototyping stage of a design, there may be a problem with noise pickup or poor layout causing the protection circuit to latch off the controller. Defeating this feature allows troubleshooting of the circuit and PC layout. The internal short-circuit and foldback current limiting still remains active, thereby protecting the power supply system from failure. A decision can be made after the design is complete whether to rely solely on foldback current limiting or to enable the latchoff feature by removing the pull-up resistor.

The value of the soft-start capacitor  $C_{SS}$  may need to be scaled with output voltage, output capacitance and load current characteristics. The minimum soft-start capacitance is given by:

$$C_{SS} > (C_{OUT})(V_{OUT})(10^{-4})(R_{SENSE})$$

The minimum recommended soft-start capacitor of  $C_{SS} = 0.1\mu F$  will be sufficient for most applications.

### Phase-Locked Loop and Frequency Synchronization

The LTC1709 has a phase-locked loop comprised of an internal voltage controlled oscillator and phase detector. This allows the top MOSFET turn-on to be locked to the rising edge of an external source. The frequency range of the voltage controlled oscillator is  $\pm 50\%$  around the center frequency  $f_0$ . A voltage applied to the PLLFLTR pin of 1.2V corresponds to a frequency of approximately 220kHz. The nominal operating frequency range of the LTC1709 is 140kHz to 310kHz.

The phase detector used is an edge sensitive digital type which provides zero degrees phase shift between the external and internal oscillators. This type of phase detector will not lock up on input frequencies close to the harmonics of the VCO center frequency. The PLL hold-in range,  $\Delta f_H$ , is equal to the capture range,  $\Delta f_C$ :

$$\Delta f_H = \Delta f_C = \pm 0.5 f_0 \quad (150\text{kHz}-300\text{kHz})$$

The output of the phase detector is a complementary pair of current sources charging or discharging the external filter network on the PLLFLTR pin. A simplified block diagram is shown in Figure 7.

If the external frequency ( $f_{PLLIN}$ ) is greater than the oscillator frequency  $f_{OSC}$ , current is sourced continuously, pulling up the PLLFLTR pin. When the external frequency is less than  $f_{OSC}$ , current is sunk continuously, pulling down the PLLFLTR pin. If the external and internal frequencies are the same but exhibit a phase difference, the current sources turn on for an amount of time corresponding to the phase difference. Thus the voltage on the PLLFLTR pin is adjusted until the phase and frequency of the external and internal oscillators are identical. At this stable operating point the phase comparator output is open and the filter capacitor  $C_{LP}$  holds the voltage. The LTC1709 PLLIN pin must be driven from a low impedance source such as a logic gate located close to the pin.

The loop filter components ( $C_{LP}$ ,  $R_{LP}$ ) smooth out the current pulses from the phase detector and provide a stable input to the voltage controlled oscillator. The filter components  $C_{LP}$  and  $R_{LP}$  determine how fast the loop acquires lock. Typically  $R_{LP} = 10k\Omega$  and  $C_{LP}$  is  $0.01\mu F$  to  $0.1\mu F$ .

Figure 7. Phase-Locked Loop Block Diagram

### Minimum On-Time Considerations

Minimum on-time  $t_{ON(MIN)}$  is the smallest time duration that the LTC1709 is capable of turning on the top MOSFET. It is determined by internal timing delays and the gate charge required to turn on the top MOSFET. Low duty cycle

## APPLICATIONS INFORMATION

applications may approach this minimum on-time limit and care should be taken to ensure that:

$$t_{ON(MIN)} < \frac{V_{OUT}}{V_{IN}(f)}$$

If the duty cycle falls below what can be accommodated by the minimum on-time, the LTC1709 will begin to skip cycles resulting in variable frequency operation. The output voltage will continue to be regulated, but the ripple current and ripple voltage will increase.

The minimum on-time for the LTC1709 is generally less than 200ns. However, as the peak sense voltage decreases, the minimum on-time gradually increases. This is of particular concern in forced continuous applications with low ripple current at light loads. If the duty cycle drops below the minimum on-time limit in this situation, a significant amount of cycle skipping can occur with correspondingly larger current and voltage ripple.

If an application can operate close to the minimum on-time limit, an inductor must be chosen that has a low enough inductance to provide sufficient ripple amplitude to meet the minimum on-time requirement. *As a general rule, keep the inductor ripple current of each phase equal to or greater than 15% of  $I_{OUT(MAX)}$  at  $V_{IN(MAX)}$ .*

### Efficiency Considerations

The percent efficiency of a switching regulator is equal to the output power divided by the input power times 100%. It is often useful to analyze individual losses to determine what is limiting the efficiency and which change would produce the most improvement. Percent efficiency can be expressed as:

$$\% \text{Efficiency} = 100\% - (L1 + L2 + L3 + \dots)$$

where L1, L2, etc. are the individual losses as a percentage of input power.

Although all dissipative elements in the circuit produce losses, four main sources usually account for most of the losses in LTC1709 circuits: 1)  $I^2R$  losses, 2) Topside MOSFET transition losses, 3)  $INTV_{CC}$  regulator current and 4) LTC1709  $V_{IN}$  current (including loading on the differential amplifier output).

1)  $I^2R$  losses are predicted from the DC resistances of the fuse (if used), MOSFET, inductor, current sense resistor, and input and output capacitor ESR. In continuous mode the average output current flows through L and  $R_{SENSE}$ , but is “chopped” between the topside MOSFET and the synchronous MOSFET. If the two MOSFETs have approximately the same  $R_{DS(ON)}$ , then the resistance of one MOSFET can simply be summed with the resistances of L,  $R_{SENSE}$  and ESR to obtain  $I^2R$  losses. For example, if each  $R_{DS(ON)}=10m\Omega$ ,  $R_L=10m\Omega$ , and  $R_{SENSE}=5m\Omega$ , then the total resistance is 25m $\Omega$ . This results in losses ranging from 2% to 8% as the output current increases from 3A to 15A per output stage for a 5V output, or a 3% to 12% loss per output stage for a 3.3V output. Efficiency varies as the inverse square of  $V_{OUT}$  for the same external components and output power level. The combined effects of increasingly lower output voltages and higher currents required by high performance digital systems is not doubling but quadrupling the importance of loss terms in the switching regulator system!

2) Transition losses apply only to the topside MOSFET(s), and are significant only when operating at high input voltages (typically 12V or greater). Transition losses can be estimated from:

$$\text{Transition Loss} = (1.7) V_{IN}^2 I_{O(MAX)} C_{RSS} f$$

3)  $INTV_{CC}$  current is the sum of the MOSFET driver and control currents. The MOSFET driver current results from switching the gate capacitance of the power MOSFETs. Each time a MOSFET gate is switched from low to high to low again, a packet of charge  $dQ$  moves from  $INTV_{CC}$  to ground. The resulting  $dQ/dt$  is a current out of  $INTV_{CC}$  that is typically much larger than the control circuit current. In continuous mode,  $I_{GATECHG} = (Q_T + Q_B)$ , where  $Q_T$  and  $Q_B$  are the gate charges of the topside and bottom side MOSFETs.

Supplying  $INTV_{CC}$  power through the  $EXTV_{CC}$  switch input from an output-derived source will scale the  $V_{IN}$  current required for the driver and control circuits by the ratio (Duty Factor)/(Efficiency). For example, in a 20V to 5V application, 10mA of  $INTV_{CC}$  current results in approximately 3mA of  $V_{IN}$  current. This reduces the mid-current loss from 10% or more (if the driver was powered directly from  $V_{IN}$ ) to only a few percent.

## APPLICATIONS INFORMATION

4) The  $V_{IN}$  current has two components: the first is the DC supply current given in the Electrical Characteristics table, which excludes MOSFET driver and control currents; the second is the current drawn from the differential amplifier output.  $V_{IN}$  current typically results in a small ( $<0.1\%$ ) loss.

Other “hidden” losses such as copper trace and internal battery resistances can account for an additional 5% to 10% efficiency degradation in portable systems. It is very important to include these “system” level losses in the design of a system. The internal battery and input fuse resistance losses can be minimized by making sure that  $C_{IN}$  has adequate charge storage and a very low ESR at the switching frequency. A 25W supply will typically require a minimum of 20 $\mu$ F to 40 $\mu$ F of capacitance having a maximum of 10m $\Omega$  to 20m $\Omega$  of ESR. The LTC1709 2-phase architecture typically halves this input capacitance requirement over competing solutions. Other losses including Schottky conduction losses during dead-time and inductor core losses generally account for less than 2% total additional loss.

### Checking Transient Response

The regulator loop response can be checked by looking at the load transient response. Switching regulators take several cycles to respond to a step in DC (resistive) load current. When a load step occurs,  $V_{OUT}$  shifts by an amount equal to  $\Delta I_{LOAD}(ESR)$ , where ESR is the effective series resistance of  $C_{OUT}$ .  $\Delta I_{LOAD}$  also begins to charge or discharge  $C_{OUT}$  generating the feedback error signal that forces the regulator to adapt to the current change and return  $V_{OUT}$  to its steady-state value. During this recovery time  $V_{OUT}$  can be monitored for excessive overshoot or ringing, which would indicate a stability problem. *The availability of the  $I_{TH}$  pin not only allows optimization of control loop behavior but also provides a DC coupled and AC filtered closed loop response test point. The DC step,*

*rise time, and settling at this test point truly reflects the closed loop response.* Assuming a predominantly second order system, phase margin and/or damping factor can be estimated using the percentage of overshoot seen at this pin. The bandwidth can also be estimated by examining the rise time at the pin. The  $I_{TH}$  external components shown in the Figure 1 circuit will provide an adequate starting point for most applications.

The  $I_{TH}$  series  $R_C$ - $C_C$  filter sets the dominant pole-zero loop compensation. The values can be modified slightly (from 0.2 to 5 times their suggested values) to optimize transient response once the final PC layout is done and the particular output capacitor type and value have been determined. The output capacitors need to be decided upon because the various types and values determine the loop gain and phase. An output current pulse of 20% to 80% of full-load current having a rise time of  $<2\mu$ s will produce output voltage and  $I_{TH}$  pin waveforms that will give a sense of the overall loop stability without breaking the feedback loop. The initial output voltage step resulting from the step change in output current may not be within the bandwidth of the feedback loop, so this signal cannot be used to determine phase margin. This is why it is better to look at the  $I_{TH}$  pin signal which is in the feedback loop and is the filtered and compensated control loop response. The gain of the loop will be increased by increasing  $R_C$  and the bandwidth of the loop will be increased by decreasing  $C_C$ . If  $R_C$  is increased by the same factor that  $C_C$  is decreased, the zero frequency will be kept the same, thereby keeping the phase the same in the most critical frequency range of the feedback loop. The output voltage settling behavior is related to the stability of the closed-loop system and will demonstrate the actual overall supply performance.

## APPLICATIONS INFORMATION

### Automotive Considerations: Plugging into the Cigarette Lighter

As battery-powered devices go mobile, there is a natural interest in plugging into the cigarette lighter in order to conserve or even recharge battery packs during operation. But before you connect, be advised: you are plugging into the supply from hell. The main battery line in an automobile is the source of a number of nasty potential transients, including load-dump, reverse-battery, and double-battery.

Load-dump is the result of a loose battery cable. When the cable breaks connection, the field collapse in the alternator can cause a positive spike as high as 60V which takes several hundred milliseconds to decay. Reverse-battery is just what it says, while double-battery is a consequence of tow truck operators finding that a 24V jump start cranks cold engines faster than 12V.

The network shown in Figure 8 is the most straightforward approach to protect a DC/DC converter from the ravages of an automotive power line. The series diode prevents current from flowing during reverse-battery, while the transient suppressor clamps the input voltage during load-dump. Note that the transient suppressor should not conduct during double-battery operation, but must still clamp the input voltage below breakdown of the converter. Although the LT1709 has a maximum input voltage of 36V, most applications will be limited to 30V by the MOSFET  $BV_{DSS}$ .

Figure 8. Automotive Application Protection

### Design Example (Using Two Phases)

As a design example, assume  $V_{IN} = 5V$  (nominal),  $V_{IN} = 5.5V$  (max),  $V_{OUT} = 1.8V$  nominal,  $I_{MAX} = 20A$ ,  $T_A = 70^\circ C$  and  $f = 310kHz$ ,  $R_{SENSE1}$  and  $R_{SENSE2}$  can immediately be calculated:

$$R_{SENSE1} = R_{SENSE2} = 50mV/10A = 0.005\Omega$$

If  $L1 = L2 = 2\mu H$  the actual value of the ripple current for each channel, the following equation is used:

$$\Delta I_L = \frac{V_{OUT}}{fL} \left( 1 - \frac{V_{OUT}}{V_{IN}} \right)$$

The highest value of the ripple current occurs at the maximum input voltage:

$$\Delta I_L = \frac{1.8}{(310kHz)(2\mu H)} \left( 1 - \frac{1.8}{5.5} \right) \approx 1.95A$$

The ripple current for each inductor is 20% of each  $I_L$  at maximum output current which is conservative.

Next verify the minimum on-time of 200ns is not violated. The minimum on-time occurs at maximum  $V_{IN}$ :

$$t_{ON(MIN)} = \frac{V_{OUT}}{V_{IN(MAX)}f} = \left[ \frac{1.8V}{5.5V(310kHz)} \right] \approx 1\mu s$$

The power dissipation on the topside MOSFET can be easily estimated. Using a Siliconix Si4420DY for example;  $R_{DS(ON)} = 0.013\Omega$ ,  $C_{RSS} = 300pF$ . At maximum input voltage with  $T_j$  (estimated) =  $110^\circ C$  at an elevated ambient temperature:

$$P_{MAIN} = \frac{1.8V}{5.5V} (10)^2 \left[ 1 + (0.005)(110^\circ C - 25^\circ C) \right] \\ 0.013\Omega + 1.7(5.5V)^2 (10A)(300pF) \\ (310kHz) = 0.65W$$

## APPLICATIONS INFORMATION

The worst-case power dissipated by the synchronous MOSFET under normal operating conditions at elevated ambient temperature and estimated 50°C junction temperature rise is:

$$P_{\text{SYNC}} = \frac{5.5\text{V} - 1.8\text{V}}{5.5\text{V}} (10\text{A})^2 (1.48) (0.013\Omega) \\ = 1.29\text{W}$$

A short-circuit to ground will result in a folded back current of about:

$$I_{\text{SC}} = \frac{25\text{mV}}{0.005\Omega} + \frac{1}{2} \left[ \frac{200\text{ns}(5.5\text{V})}{2\mu\text{H}} \right] = 5.3\text{A}$$

The worst-case power dissipated by the synchronous MOSFET under short-circuit conditions at elevated ambient temperature and estimated 50°C junction temperature rise is:

$$P_{\text{SYNC}} = \frac{5.5\text{V} - 1.8\text{V}}{5.5\text{V}} (5.3\text{A})^2 (1.48) (0.013\Omega) \\ = 360\text{mW}$$

which is much less than normal, full-load conditions. Incidentally, since the load no longer dissipates power in the shorted condition, total system power dissipation is decreased by over 99%.

The duty factor for this application is:

$$\text{D.F.} = \frac{V_O}{V_{\text{IN}}} = \frac{1.8\text{V}}{5\text{V}} = 0.36$$

Using Figure 4, the RMS ripple current will be:

$$I_{\text{INRMS}} = (20\text{A})(0.23) = 4.6\text{A}_{\text{RMS}}$$

An input capacitor(s) with a 4.6A<sub>RMS</sub> ripple current rating is required.

The output capacitor ripple current is calculated by using the inductor ripple already calculated for each inductor and multiplying by the factor obtained from Figure 3 along with the calculated duty factor. The output ripple in continuous mode will be highest at the maximum input voltage since the duty factor is <50%. The maximum output current ripple is:

$$\Delta I_{\text{COUT}} = \frac{V_{\text{OUT}}}{f_L} (0.3) \text{ at } 33\% \text{ D.F.}$$

$$\Delta I_{\text{COUTMAX}} = \frac{1.8\text{V}}{(310\text{kHz})(2\mu\text{H})} 0.3 \\ = 0.87\text{A}_{\text{RMS}}$$

$$V_{\text{OUTRIPPLE}} = 20\text{m}\Omega (0.87\text{A}_{\text{RMS}}) = 17\text{mV}_{\text{RMS}}$$

### PC Board Layout Checklist

When laying out the printed circuit board, the following checklist should be used to ensure proper operation of the LTC1709. These items are also illustrated graphically in the layout diagram of Figure 11. Check the following in your layout:

- 1) Are the signal and power grounds segregated? The LTC1709 signal ground pin should return to the (–) plate of C<sub>OUT</sub> separately. The power ground returns to the sources of the bottom N-channel MOSFETs, anodes of the Schottky diodes, and (–) plates of C<sub>IN</sub>, which should have as short lead lengths as possible.
- 2) Does the LTC1709 V<sub>OS</sub><sup>+</sup> pin connect to the point of load? Does the LTC1709 V<sub>OS</sub><sup>–</sup> pin connect to the load return? The resistive divider R1, R2 must be connected between the V<sub>DIFFOUT</sub> and signal ground and any phase lead capacitor across R1 should be as close as possible to the LTC1709.
- 3) Are the SENSE<sup>–</sup> and SENSE<sup>+</sup> leads routed together with minimum PC trace spacing? The filter capacitors between SENSE<sup>+</sup> and SENSE<sup>–</sup> pin pairs should be as close as possible to the LTC1709. Ensure accurate current sensing with Kelvin connections at the current sense resistor.

## APPLICATIONS INFORMATION

4) Does the (+) plate of  $C_{IN}$  connect to the drains of the topside MOSFETs as closely as possible? This capacitor provides the AC current to the MOSFETs. Keep the input current path formed by the input capacitor, top and bottom MOSFETs, and the Schottky diode on the same side of the PC board in a tight loop to minimize conducted and radiated EMI.

5) Is the  $INTV_{CC}$  1 $\mu$ F ceramic decoupling capacitor connected closely between  $INTV_{CC}$  and the power ground pin? This capacitor carries the MOSFET driver peak currents. A small value is used to allow placement immediately adjacent to the IC.

6) Keep the switching nodes, SW1 (SW2), away from sensitive small-signal nodes. Ideally the switch nodes should be placed at the furthest point from the LTC1709.

7) Use a low impedance source such as a logic gate to drive the PLLIN pin and keep the lead as short as possible.

The diagram in Figure 9 illustrates all branch currents in a 2-phase switching regulator. It becomes very clear after studying the current waveforms why it is critical to keep the high-switching-current paths to a small physical size. High electric and magnetic fields will radiate from these "loops" just as radio stations transmit signals. The output capacitor ground should return to the negative terminal of the input capacitor and not share a common ground path with any switched current paths. The left half of the circuit gives rise to the "noise" generated by a switching regulator. The ground terminations of the synchronous MOSFETs and Schottky diodes should return to the negative plate(s) of the input capacitor(s) with a short isolated PC trace since very high switched currents are present. A separate isolated path from the negative plate(s) of the input capacitor(s) should be used to tie in the IC power ground pin (PGND) and the signal ground pin (SGND). This technique keeps inherent signals generated by high current pulses from taking alternate current paths that have finite impedances during the total period of the switching regulator. External OPTI-LOOP compensation allows over-compensation for PC layouts which are not optimized but this is not the recommended design procedure.

### Simplified Visual Explanation of How a 2-Phase Controller Reduces Both Input and Output RMS Ripple Current

A multiphase power supply significantly reduces the amount of ripple current in both the input and output capacitors. The RMS input ripple current is divided by, and the effective ripple frequency is multiplied up by the number of phases used (assuming that the input voltage is greater than the number of phases used times the output voltage). The output ripple amplitude is also reduced by, and the effective ripple frequency is increased by the number of phases used. Figure 10 graphically illustrates the principle.

The worst-case RMS ripple current for a single stage design peaks at an input voltage of twice the output voltage. The worst-case RMS ripple current for a two stage design results in peak outputs of 1/4 and 3/4 of input voltage. When the RMS current is calculated, higher effective duty factor results and the peak current levels are divided as long as the currents in each stage are balanced. Refer to Application Note 19 for a detailed description of how to calculate RMS current for the single stage switching regulator. Figures 3 and 4 help to illustrate how the input and output currents are reduced by using an additional phase. The input current peaks drop in half and the frequency is doubled for this 2-phase converter. The input capacity requirement is thus reduced theoretically by a factor of four! Ceramic input capacitors with their unbeatably low ESR characteristics can be used.

Figure 4 illustrates the RMS input current drawn from the input capacitance vs the duty cycle as determined by the ratio of input and output voltage. The peak input RMS current level of the single phase system is reduced by 50% in a 2-phase solution due to the current splitting between the two stages.

An interesting result of the 2-phase solution is that the  $V_{IN}$  which produces worst-case ripple current for the input capacitor,  $V_{OUT} = V_{IN}/2$ , in the single phase design produces zero input current ripple in the 2-phase design.

## APPLICATIONS INFORMATION

The output ripple current is reduced significantly when compared to the single phase solution using the same inductance value because the  $V_{OUT}/L$  discharge current term from the stage that has its bottom MOSFET on subtracts current from the  $(V_{IN} - V_{OUT})/L$  charging current resulting from the stage which has its top MOSFET on. The output ripple current is:

$$\Delta I_{RIPPLE} = \frac{2V_{OUT}}{fL} \left[ \frac{|1-2D|(1-D)}{|1-2D|+1} \right]$$

where D is duty factor.

The input and output ripple frequency is increased by the number of stages used, reducing the output capacity requirements. When  $V_{IN}$  is approximately equal to  $2(V_{OUT})$  as illustrated in Figures 3 and 4, very low input and output ripple currents result.

## PACKAGE DESCRIPTION

Dimensions in inches (millimeters) unless otherwise noted.

**G Package**  
**36-Lead Plastic SSOP (0.209)**  
 (LTC DWG # 05-08-1640)

NOTE: DIMENSIONS ARE IN MILLIMETERS  
 \*DIMENSIONS DO NOT INCLUDE MOLD FLASH. MOLD FLASH SHALL NOT EXCEED 0.152mm (0.006") PER SIDE  
 \*\*DIMENSIONS DO NOT INCLUDE INTERLEAD FLASH. INTERLEAD FLASH SHALL NOT EXCEED 0.254mm (0.010") PER SIDE

G36 SSOP 1098

## TYPICAL APPLICATION
