

the reticuloendothelial system without participation of the other potentialities of the system, yielding a unique monocytic cell. Both extramedullary and medullary proliferation concerns exclusively this type of cell. The experimental condition produced by me corresponds to the form known in human pathology as Schilling's monocytic leukemia. This germinative line of leucocytes has therefore in pathology its meaning and importance, as Virchow claimed.

These experimental results may be considered in the light of what we know with respect to the origin of certain neoplasms, so-called "conditioned" that are best known in the field of endocrinology. Leukemogenesis is a type of carcinogenesis (Furth) and therefore the concepts referred to the growth of conditioned neoplasms can be extended to experimentally ascertained events that move in the direction of leukemia.

Copper Fluorides

A recent paper of Crabtree, Lees, and Little (1) reports in part on an x-ray study of the fluorides of copper. Reference is made to an earlier paper by Ebert and Woitinek (2), the conclusions of which are questioned. In attempting to explain the original error, the recent authors have confused the situation by further error and misinterpretation.

The complete explanation had previously been published (3). In brief, the original "CuF," $a = 4.26$ Å, ZnS structure, was apparently Cu_2O , $a = 4.25$ Å, Cu_2O structure. "CuF₂," $a = 5.41$ Å, CaF_2 structure, was apparently CuCl , $a = 5.41$ Å, ZnS structure. The comparison becomes obvious when the interplanar spacings are calculated, taking into account the extinctions characteristic of the different structural types. Direct comparison of lattice constants is not advisable since the structure types being compared are not the same, contrary to the statement by Crabtree *et al.* (1). The general extinctions of space groups $F\bar{4}3m$ (CuCl) and $Fm\bar{3}m$ ("CuF₂") are the same, but those of $F\bar{4}3m$ ("CuF") and $Pn\bar{3}m$ (Cu_2O) are not.

To complicate matters further, reference is made to cupric chloride, CuCl_2 , with lattice dimension 5.4075 kx, where CuCl , $a = 5.4057$ Å (4) is meant. Cupric chloride has the monoclinic CuBr_2 structure.

The structure of cupric fluoride, CuF_2 , has been determined here by Claudine Billy. It is monoclinic, $a = 3.325 \pm 0.005$ Å,

$b = 4.544 \pm 0.005$ Å, $c = 4.578 \pm 0.005$ Å, $\beta = 83^\circ 17'$. Details will be submitted elsewhere for publication.

Paleotemperatures of Pacific Bottom Waters and Multiple Hypotheses

Cesare Emiliani's recent article on the temperature decrease of Pacific bottom waters during the Tertiary (1) is not only a very interesting and important contribution but one that stimulates many lines of thought. Using the method of oxygen isotope analysis, he has analyzed the benthonic Foraminifera of three cores from the eastern Pacific, which he reports as Oligocene, Miocene, and late Pliocene, indicating a temperature decrease of about 8°C from the middle of the Oligocene to the end of the Pliocene. Emiliani's conclusions are predicated on at least two critical assumptions that permit additional postulates. He assumed, in the first case, that one or two species dated the entire fauna in *Albatross* cores 53 and 57 and, in the second case, that the entire fauna analyzed lived in the same abyssal depths as the one or two key species.

Concerning the first assumption regarding age data, Emiliani states that the Middle Oligocene age of core number 53 is well established because of the presence of typical specimens of *Cassidulina spinifera* Cushman and Jarvis in all of the samples of the core. He reports that Oligocene and Miocene sediments were available for coring in cores 53 and 57 because submarine erosion or slumping had previously eliminated the younger sediments. It should be pointed out that *Cassidulina spinifera* or one almost identical with it occurs in association with modern species in the Marshall Islands at depths of 710 and 680 fathoms (2). There are many typical specimens of this species in the collections of the Allan Hancock Foundation, all from Recent assemblages collected in the Marshall Islands. Other reports indicate that this species is no older than Pliocene in the Pacific area (3). Cushman and Stainforth also recognize discrepancies in the correlations between Trinidad and the Pacific area. In a report on *Cassidulina spinifera* and the associated microfauna of the type locality for this species (Oli-

gocene, Cipero formation, Trinidad), they speak of the striking similarities between the Cipero species and those of the late Tertiary of the Indo-Pacific region. They also mention T. W. Vaughan's comments regarding the affinities between the Oligocene corals of Trinidad and the living species of the Indo-Pacific area (4).

Next, Emiliani states that the age of core 57 is established as lower-middle Miocene because of the presence of *Gyroidina zelandica* Finlay, together with *Laticarinina bullbrooki* Cushman and Todd. This species of *Gyroidina* is very similar to variations of *G. soldanii* that range from well back in the Tertiary to Recent. As for *Laticarinina bullbrooki*, the very authors of this species state, "A very similar, perhaps identical, species occurs in some numbers at *Albatross* D 2144 at 896 fathoms in the Caribbean Sea off Panama" (5).

Arrhenius (6) analyzed core 58 by the titanium method of age determination, and the Pliocene sample in Emiliani's report was taken from just below the probable Pleistocene core segment thereof.

Turning to the second assumption, that the faunas are abyssal, again raises a question. One might postulate that the same results might be achieved with displacement of shallow water faunas instead of decreasing bottom temperatures. If the faunas were displaced from depths of about 500 m or less, the temperatures there are mostly above 7°C , and so isotopic analyses would produce results that would be within the range reported by Emiliani for the Oligocene and Miocene cores. True, the key species include two that are most likely abyssal in habit (*Laticarinina bullbrooki* and *Gyroidina zelandica*); however, the remaining faunas in the two cores may include shallow benthonic species, and these would in turn affect the results. *Cassidulina spinifera* occurs in the Oligocene of Trinidad with an upper bathyal fauna, and it also occurs in modern sediments on the flanks of some of the seamounts of the Pacific along with modern species. Whether or not this species is fossil and/or displaced, it is inconclusive evidence that the associated species in the isotope analyses are Oligocene or abyssal.

On the basis of the published report, there is a reasonable doubt concerning the ages of samples 53 and 57 and there is similarly little reason for indicating ages of faunas based on one or two species of faunas that are taken from the surface sediments of the sea bottom. An excellent example of possible pitfalls of this kind is demonstrated by Hamilton in his paper on the mid-Pacific seamounts (7). He reports mixtures of Cretaceous to Recent species in a sample taken at 2050 fathoms at latitude $19^\circ 34'\text{N}$, longitude $171^\circ 54'\text{W}$ near the
